# Disaggregation Methods to Expedite Product Line Forecasting

CHARLES W. GROSS and JEFFREY E. SOHL University of New Hampshire, USA

#### **ABSTRACT**

This paper addresses the issue of forecasting individual items within a product line; where each line includes several independent but closely related products. The purpose of the research was to reduce the overall forecasting burden by developing and assessing schemes of disaggregating forecasts of a total product line to the related individual items. Measures were developed to determine appropriate disaggregated methodologies and to compare the forecast accuracy of individual product forecasts versus disaggregated totals. Several of the procedures used were based upon extensions of the combination of forecast research and applied to disaggregations of total forecasts of product lines. The objective was to identify situations when it was advantageous to produce disaggregated forecasts, and if advantageous, which method of disaggregation to utilize. This involved identification of the general conceptual characteristics within a set of product line data that might cause a disaggregation method to produce relatively accurate forecasts. These conceptual characteristics provided guidelines for forecasters on how to select a disaggregation method and under what conditions a particular method is applicable.

differential

As an organization expands, its sales forecasting activities often escalate in scope to become a very burdensome set of tasks. Various forecasts may be required, including: multiple forecasts under different planning horizons—the immediate, short, medium and long term (Wheelwright and Makridakis, 1985); several aggregate forecasts—for entire product lines, divisions, the total organization and for the entire industry(s) in which the firm competes (Armstrong, 1985); and numerous disaggregate forecasts at the individual product and product/market segment levels for inventory management, product scheduling, advertising planning and similar short-range decision making (Willis, 1987; Hurwood et al., 1978; Day, 1977).

Perhaps the greatest forecasting effort stems from the generation of these disaggregate forecasts due to the very large number of forecasts potentially involved. To illustrate, a firm 0277-6693/90/030233-22\$11.00

that markets ten product lines, with each containing 50 products and with each being marketed to five different markets, requires that  $10 \times 50 \times 5 = 2500$  separate forecasts are needed each period if the disaggregate level is to be estimated.

To effectively manage the voluminous forecasting task, managers have the following options; listed in order of increasing burden (Dalrymple, 1987):

- (1) Forecast the total aggregates, then disaggregate these totals to the individual products and/or markets according to some predetermined weighting scheme. This option involves the least amount of effort.
- (2) Forecast individual disaggregates for each unit, then sum them to provide the aggregate forecasts. This option portrays a middle ground in terms of the required forecasting work effort.
- (3) Provide separate forecasts for all levels of concern, and ignore whether or not each of the separate forecasts sum to the aggregates. This option involves the greatest level of work, but it is likely to lead to the greatest level of forecasting accuracy due to the customization of individual models.

In choosing which option to follow, management must assess the trade-off between (a) the perceived benefits derived from generating separate forecasts (usually defined in terms of greater forecast accuracy) and (b) the economies derived from some disaggregation scheme that, presumably, involves lowering forecast accuracy.

This paper examines whether or not the extensive literature which combines forecasts from different models, with each forecasting a single data series, may be extended to the application of accurately disaggregating forecasts within a product line. The purpose is to examine possible methods of reducing the overall forecasting burden by focusing on the first alternative—the development of reasonably accurate disaggregation methods.

# DATA AND VARIABLES

Data were obtained from the Metal Products Division of USG Industries, Inc. (a subsidiary of US Gypsum, Inc.). Three major industrial galvanized steel product lines were examined, which were distributed internationally. 'Grip strut' was a type of steel industrial flooring material that contained stamped, diamond-patterned perforations which provided a non-slip surface for areas such as catwalks, platforms and decks. There were seven product categories within this line (referred herein as GS1, GS2,...,GS7), each with differing dimensions. 'Channel' comprised heavy-gauged steel tracks used primarily to house electrical cable in industrial areas. There were three product categories within channel (CH1, CH2 and CH3), each with varying dimensions. Finally, 'Accessories' (ACC1, ACC2,...,ACC5) comprised various connectors and fittings used to assemble and install channel products.

Data collected were for the period January 1983 to May 1987, which provided a total of 18 monthly time series with 53 observations each. Unit sales were used in place of dollar sales to eliminate any price-related exogenous effects (Schnaars, 1986). An initial examination revealed very low correlations among the sales of all products, both within and between the product lines. Thus, all products were treated as independent in the analysis, suggesting the construction of separate forecasting models for each time series.

#### **METHOD**

The study compared the results of various disaggregation methods that were applied to each product line with individually generated, optimal forecasts to assess the extent of any loss in forecast accuracy. Procedures used to evaluate the question of using total versus individual forecasts are developed in this section. Results for all the product lines examined are presented in the Empirical Results section below.

# Individual forecasting procedures

While several error measurements were available (Wheelwright and Makridakis, 1985), the root mean square error (RMSE) was considered the most meaningful to compare forecasting models on the raw series because of its simplicity and ability to weight heavily the magnitude of error. Further, use of the mean absolute percentage error (MAPE) was rejected. Several of the individual products contained zero or near-zero reported sales for various periods (i.e. MAPE would be undefined) due to a combination of low reported sales in some periods and the practice of netting sales returns with new sales. No attempt was made to adjust sales in previous periods for such sales returns as the details were irretrievable from the company's records.

Several forecasting models were considered for each series, including: exponential smoothing (ES) (single, double, Holt's two parameter, Winters' additive and multiplicative, and quadratic), time series regression (linear, quadratic and logarithmic), and two deseasonalization schemes (classical—method 1, modified Census II—method 2; as described in Gross and Peterson, 1983). Least squares procedures were used to initialize ES models (derived in Brown, 1963; detailed in Gross and Peterson, 1983). All the forecasting models were also designed to calculate and use optimal weights. These models were chosen because they appeared to be the best predictors for relatively short-term time series (Granger and Newbold, 1977), were relatively simple to use and they have been shown to be mathematically equivalent to several Box—Jenkins specifications (Bowerman and O'Connell, 1987; McKenzie, 1984; Ledolter and Abraham, 1984). The forecasting models used are summarized in Appendix 1.

Reducing RMSE was the objective established for selecting which particular forecasting model to choose for a given series, though additional criteria were also used. Each identified model was applied to two distinct phases to test model stability against known actual values. The models were first applied to periods 1 through 42 of each series and used to forecast the actual values for periods 43 through 48. The models were also applied to periods 1 through 48 and used to forecast values for periods 49 through 53. Each identified model was examined to assure that an appreciable inflation in the RMSE did not occur within the forecast phases. Finally, each model was applied to all 53 periods both to assess the reasonableness of the RMSEs and to update the coefficients. Further, the autocorrelations of the errors were examined during testing within each phase to assure that they resembled 'white noise' Table 1 provides a list of the final models used and their associated RMSEs at various stability-testing phases. Thus, the models used were generally quite stable.

There were a total of twelve different models chosen on the basis of the above criteria to forecast the eighteen series, as illustrated in Table 1. While such diversity might not be expected in many applications, in this case the variety of models used to produce the individual forecasts was considered reasonable. Many of the individual products were targeted toward specific, independent market segments and, naturally, were expected to evidence different sales patterns. Since the markets were quite dissimilar, it appeared reasonable that different models would be useful for forecasting sales. It is worth noting, however, that all the models chosen were members of three basic families of models and situations; no trend, linear trend and additive

Root mean square error for within-data forecasts.

trend. Thus, the models used were not unrelated to each other, nor were they assigned by chance.

While models were carefully selected according to the stated criteria, the resulting forecasts were viewed as givens. Thus, the primary focus of the study was directed to the various disaggregation methods evaluated below.

#### Proportional disaggregation methods

Twenty-one different proportional disaggregation schemes were examined in the study and included simple averages of the sales proportions, lagged proportions and combined lagged proportions. The methods used are summarized in Appendix 2. The procedures used had their foundation in the forecasting combination literature (for a summarized review of various combination methods, see Mahmoud, 1984). That literature addressed the issue of evaluating methods of combining forecasts, both subjective and objective, for a single time series. In this study these combination methods were extended to product line forecasting.

Methods A and F were based on the simple average (equal weights) of a product's share of

<sup>&</sup>lt;sup>b</sup> Root mean square error for actual forecasts.

total product line sales, over the entire historical period (Makridakis and Winkler, 1983). Method A was constructed to reflect the mean proportion that a given product represented of the total product line's sales. Method F was structured to represent the proportion that a given product's sales represented of the overall product line's mean sales.

Methods B1 through B4 were based upon the conjecture that the proportions of previous time periods were the best predictors for the next period's proportion of total sales. Thus, method B1 used a product's proportion in period t-1 as the disaggregation measure for period t. Similarly, methods B2 through B4 utilized two-, three- and four-period lags, respectively, for disaggregating a product line forecast to individual products. Method C attempted to capture trends in the proportions through a moving average of two-, three- and four-period lagged proportions (methods C2, C3 and C4).

The remaining disaggregation schemes investigated the use of differential weights. Methods D2 through D4 combined lagged proportions (lags of two, three and four periods, respectively) using weights based upon the correlations between the lag and the current period's proportion. These weights were formed by dividing each lag's correlation by the sum of all the correlations under consideration, with lags having the highest correlation receiving the maximum weight, the next highest the next largest weight, etc. (Ashton and Ashton, 1985).

In method E a regression model was used to determine the weights assigned to each lag (Bopp, 1985; Granger and Newbold, 1977). A restriction was imposed that the regression coefficients sum to 1.0 to maintain consistency between the differential weighting methods.

Methods G and H considered differential weights based upon the variance and the covariance of the errors (Bates and Granger, 1969; Newbold and Granger, 1974). In the context of our research, the error for lag one was defined as the difference between the actual sales proportion in period t and t-1. Likewise, for lag two, the difference between actual sales proportion in period t and t-2 was considered the lag-two error. Methods G2 and G3 (lags one and two, and lags one, two and three, respectively) combined the lagged proportions with differential weights based on the variance and covariance of the error terms. The lagged pair with the smallest variance—covariance structure was given the largest weight, with decreasing weights assigned accordingly. Methods H2 and H3 were similar to method G, except that the weights were based on the variance of the errors.

Method I was similar to method D with differential weights based on the correlation between a lag's proportion and the current period's proportion. However, in method I2 (for example), the two lags having the highest correlation with the current period's lag were combined, with the differential weights based on the value of the correlation, and with the weights then normalized. Method I3 considered the three lags with the largest correlations and method I4 combined four lags. Thus, method I chose the best predictors of the current proportion and used a differential moving average to combine the weights as a means of identifying trends.

## Comparison procedure

Let P denote the proposition used for disaggregating the total forecast. Then, to obtain a prorated forecast from the total:

$$F_{it} = P_{it}T_t$$

where

 $F_{ii}$  = forecast of product i for period t, using  $P_{ii}$  as the weighting scheme,

 $T_t$  = total forecast for all products in the line for period t,

 $P_{it}$  = the proportion used to allocate product i's share of the total forecast at time t,

t = 1, 2, 3, ..., n,

n = total number of time periods,

i = 1, 2, 3, ..., N

N = total number of products within the product line.

The corresponding RMSE for the prorated forecast (RMSEP) for product i is:

RMSEP<sub>i</sub> = 
$$\left\{ \frac{\sum_{t=1}^{n} (X_{it} - F_{it})^{2}}{n} \right\}^{1/2}$$

where

238

 $X_{it}$  = actual sales for product i in period t.

To compare the RMSE from a given weighting scheme with the RMSE for the identified optimal individual product forecasting model, we defined:

$$D_i = RMSEP_i - RMSE_i$$

where

 $RMSE_i$  = the root mean square error for the individual product i model,

 $D_i$  = the root mean square error differential.

A positive  $D_i$  indicated that, for product i, the RMSE from the individual forecast was lower than the RMSE for the disaggregated total and, thus, implied that better forecasting was possible using a model fit specifically to product i sales data, rather than using total sales and then disaggregating. In contrast, a negative score indicated the opposite: that a better result was possible by first forecasting the total, then disaggregating according to the applicable proportional scheme (Mathews and Diamantapoulos, 1986).

## Composite measure

A composite measure was designed to provide a summary statistic for an entire product line and for a given decomposition procedure. This was obtained by weighting each different RMSE by the average proportion of an individual product's sales to the total sales of that product line. Specifically,

$$CD = \sum_{i=1}^{N} D_i \overline{PR_i}$$

where

CD =composite root mean square error differential,

 $PR_i$  = average proportion of total product line sales for product i

For the composite measure, a negative CD suggested that relatively accurate forecasts were possible through a procedure of first forecasting the total product line and then disaggregating such a total according to the relative proportional scheme. A positive CD suggested the opposite: that more accurate forecasts resulted from separately forecasting each product within the line as well as the line's total sales. A CD of zero (or close to zero) suggested indifference between the two approaches in terms of accuracy. The CD coefficients also provided a means of evaluating various proportional allocation schemes under a disaggregation strategy. The most negative (or least positive) CD corresponded to the disaggregation scheme resulting in the lowest RMSE. Thus, the selection of a proportional method was not relegated to some arbitrary

choice and the composite measure provided a means for management to assess the impact on forecast accuracy if a disaggregation scheme were selected over forecasting at the individual product level.

#### **EMPIRICAL RESULTS**

Tables 2 and 3 summarize the results of the study. Three sets of CD scores for each product line are shown in Table 2; for periods 1 through 42, 1 through 48 and 1 through 53. It is apparent in the table that the CD scores remained relatively stable between each of the phases used to test model stability. As expected, because reducing RMSE was a primary objective used in their selection, the individual forecasting models were superior to the disaggregation models for all product lines. This is indicated in Table 2 by the generally positive CD scores.

Table 3 presents the results of directly examining the forecasts produced by the disaggregation methods. The RMSEs for each model relative to forecasts of periods 43 through 48 based on actual data from periods 1 through 42 are presented in Part A of the table. Part B contains the results of forecasting periods 49 through 53 on the basis of actual data in periods 1 through 48. For comparison, the RMSEs for the corresponding time period, based upon using the individual optimal model for each product (Table 1), are presented at the top portion of each table. The measures presented in Table 3, therefore, illustrate the net forecast accuracy of each disaggregation method for each product over two forecast phases. Again, there is a high

degree of model stability between periods, as well as consistency with the methods identified as performing well on the basis of *CD* scores, as reported in Table 2.

The remaining question was whether any incremental error was large compared to the efficiencies gained by adopting a disaggregation strategy. For the grip strut product line, methods A and F performed reasonably well, with the CD scores close to zero, and forecasts nearly as good as the optimal individual model forecasts. Methods I3 and I4 produced slightly higher CD scores then did methods A and F, though their results were also quite good. On the basis of forecast accuracy alone, therefore, one would have been relatively indifferent between between using one of these four proportional schemes and preparing separate forecasts. Considering the effort required to generate individual forecasts on an ongoing basis, however, one of the four proportional schemes (A, F, I3 or I4) would have likely been selected. The routine forecasting task would then have been reduced from detailed analyses of eight separate series (one for each product plus one for the total line) to one series (the total), which would then have been disaggregated on the basis of the selected proportional scheme.

Disaggregating procedures also appeared promising for the accessory products. As Table 2 illustrates, method I3 and I4 generated slightly negative *CD* measures for periods 1 through 48 and 1 through 53. Similarly, their resulting forecasts were relatively accurate as compared with the individual optimal models (Table 3). These factors suggested that disaggregation would have been favorable for accessory products. While the results by no means imply that forecasting accuracy could generally be improved by using disaggregational methods, nonetheless they did indicate that the errors might not deteriorate much, if at all, by so doing, and at a significantly reduced computational effort.

The opposite conclusion was reached for the channel product line. As Tables 2 and 3 illustrate, the CD measures were both large and positive for each of the proportional schemes examined, and the RMSEs were generally much larger than those derived from the individual optimal models. Thus, routinely performing separate product forecasts (for individual products as well as for the line's total sales) substantially improved overall forecast accuracy for channel products. Accordingly, management would not likely have chosen any proportional disaggregating scheme for forecasting channel products.

# WHY DISAGGREGATION IS APPLICABLE IN SOME CASES

The results of this study represented the findings of three particular cases of one company. As a result, it was difficult to generalize the findings to other cases. However, attention was directed to understanding why disaggregation was applicable for the grip strut and accessories product lines but not for the channel line. This involved an in-depth analysis of the data sets to discover the common characteristics of those series where disaggregation appeared to work well. First, we considered the general conceptual characteristics within a set of product line data which might cause a disaggregation method to become relatively accurate. Second, we examined the results of this study in light of the general conceptual characteristics to learn if they were consistent with the findings.

# Conceptual characteristics favoring disaggregation

In general, the applicability of a disaggregation procedure was considered a function of three factors: (1) the accuracy of the total product line forecast, (2) the accuracy of the proportion used in conjunction with the size of the individual product's share of the total product line's sales, and (3) the degree of accuracy attained in forecasting at the individual product level.

Although these factors were interconnected, an apparent hierarchical structure emerged to provide guidelines for determining whether or not disaggregation would seem operationally feasible.

At the first level, both the direction and the magnitude of the total product line forecast accuracy was considered. Given an accurate total forecast, the second level was to examine the magnitude of the errors of the estimated proportions used to allocate a product's share of the total forecast and the individual product's average share of the total product line's sales. The larger a product's share, the greater the accuracy required for the estimated proportions. If a total forecasting model consistently under- or overestimated the total product line's sales, then a disaggregation method whose estimated proportions was biased in the direction opposite to that of the total model should have tended to yield accurate disaggregated forecasts. This bias should have also been most prominent for those products with the largest share of the total product line's sales. For cases where the total forecast was inaccurate with no distinguished direction for the bias there appeared to be little hope for a disaggregation procedure to yield promising results. Specifically, for the second level to have provided accurate forecasts, the estimated proportions for the major products would have needed to have been accurate, at a minimum, to avoid compounding the effect of a poor total forecast, or have been biased in a compensating direction to have mitigated the effect of a poor total forecast. In general, the chances of this optimal matching appeared to be minimal.

Given satisfactory results at the first two levels, the third level addressed the degree of accuracy attained in forecasting at the individual product level. If an individual product forecasting model demonstrated a poor forecasting performance (a high RMSE relative to other products in the product line), then a disaggregated forecast needed only to perform better than this benchmark. The implication was that if an individual series was inherently difficult to forecast, the difficulty should have been considered when assessing the forecasting performance of the disaggregation procedure.

In summary, the critical issues for conceptually determining the usefulness of pursuing a disaggregation strategy to product line forecasting was an identification of the situation when it appeared advantageous to use a disaggregation method and, if advantageous, which method of disaggregation to have utilized. The three-level structure discussed above provided conceptual guidelines for assessing the appropriateness of disaggregation. Given that the hierarchical structure identified candidates for disaggregation, the composite differential measure was used to identify which of the disaggregation procedures appeared most applicable.

## **Empirical assessment**

The results were examined in light of the above three conceptual determinants (factors). At the first level, Table 4 summarizes both the direction and the magnitude of the total product line forecast accuracy for comparable periods examined in previous tables. The total sales of the grip strut product line was forecast relatively accurately, with between 60% and 74% of the total forecasts within 20% of actual sales during corresponding time periods. This implied that for grip strut, the appropriateness of disaggregation was largely determined by the accuracy of the proportions for those individual products with a substantial share of the total product line's sales (level two). For disaggregation procedures A and F, over 90% of the forecasted proportions were within approximately 10% of the actual individual products' market share over all time periods. Thus, the accurate disaggregation achieved by methods A and F combined with a stable and consistent total forecast resulted in the low composite measures. In addition, each of the disaggregated models generally compared favorably to the benchmark RMSEs of the individual models (Tables 1 and 3).

a Within-data forecasts

For accessories, Table 4 indicates that the total forecasting model consistently overestimated the actual total product line sales. Since the bias was unidirectional, a disaggregation method whose estimated proportions were biased in the opposite direction for those products with the largest share of total product line sales should have produced accurate disaggregated forecasts. Two accessory products (one and four) accounted for, on average, 89% of the product line's sales. For disaggregation methods I3 and I4, the proportions for product four were underestimated when the total forecast was above the actual, and accurate (within 10% of the actual) when the difference between the actual and the total forecast was small. These optimal matches of estimated proportions and total product line sales forecasts combined to produce relatively accurate disaggregated forecasts. For accessory product one, the estimated proportions derived from methods I3 and I4 did not demonstrate the clear bias that existed for product four. However, product one's sales was an inherently difficult series to forecast, as evidenced by the high RMSE for the individual model (Table 1). Thus, in a relative sense, product one's

<sup>&</sup>lt;sup>b</sup> Actual forecasts

disaggregated model produced more accurate results for a difficult series to forecast than did the individual forecasting model.

For the channel product line, Table 4 indicates that the total forecasting model was a relatively poor predictor of total sales, with approximately an equal number of forecasts being above, below or within 10% of the actual. In addition, for the disaggregated models, the products with the largest share of total sales yielded the least accurate estimated proportions. Thus, this combination of poor total forecasts and inaccurate disaggregation models offered little hope for a disaggregation procedure to yield promising results for the channel product line.

#### CONCLUSIONS

This paper has focused on the problems associated with forecasting sales within companies that sell several products within many product lines. The large number of items to forecast, plus the fact that there are often different forecast requirements within the firm itself, can lead to an unmanageable set of forecasting tasks or the adoption of relatively unsophisticated, inaccurate disaggregation techniques.

The purpose of the study was to identify ways of reducing the overall forecasting burden by developing and assessing schemes of disaggregating forecasts of the total related product line to the individual items without a significant deterioration in forecast accuracy. Several of the procedures used were based upon extensions of the combination of forecast research to disaggregations of total forecasts within a product line. Measures were developed to determine appropriate disaggregation methodologies and to compare the forecast accuracy of individual product forecasts versus disaggregated totals.

Three disaggregation procedures appeared most promising in this particular application: A, F and I. Two of the methods, A and F, were based on the simple average (equal weights) of the products' share of total product line sales over the entire historical period. They were also simple to calculate, implement and update as more data became available. The third method, I, was based on a differential weighting procedure, with weights corresponding to the correlation between the lag sales proportion and the current period's proportion. The method chose the best predictors of the current proportion and used a differential moving average to combine the weights as a means of identifying trends. Although method I involved more calculation than A or F, it possessed intuitive appeal, was readily updated and could be automated to require minimal user interaction.

Because the results were based upon the findings of three particular cases of one company, they were difficult to generalize to other situations. However, attention was directed to understanding why disaggregation was applicable to two of the product lines examined and not for the third. This involved analyzing the data set to uncover the common characteristics of those series where disaggregation worked well. The general conceptual characteristics were considered and a three-level hierarchical structure emerged as a means for providing guidelines for the applicability of disaggregation. The results of the study were examined in light of the general conceptual characteristics and were discovered to be consistent with these findings.

To assure the generalizability of the results, the study would have to be replicated for several additional product/industry combinations. Clearly, generating forecasts with disaggregation methods that both reduce the forecasting burden and enable reasonably accurate results will increase the application of forecasting procedures among large-scale, multi-product organizations.

# APPENDIX 1: FORECASTING MODELS USED

#### General notation

246

 $X_t =$ actual sales value at time period t

 $F_t$  = forecast of sales at time period t

n = the number of time periods in the series

a = intercept estimate

b = slope estimate

c = rate of change estimate

 $s_t = a$  seasonal factor relating to time t

L = number of seasons in one year

l = a particular season in a year (e.g. March, quarter 3, etc.), and l = 1 to L

 $\alpha$  = a weighting constant, where  $0 \le \alpha \le 1.0$ , and optimal (based on min. RMSE)

 $\beta = 1.0 - \alpha$ 

OLSQ = ordinary least squares

# (A) Horizontal (no) trend

(1) Mean

$$F_t = \sum X_t/N$$
 For  $t = 1, 2, ..., n$ 

(2) Single exponential smoothing:

$$F_{t+1} = \alpha_{\text{opt}} X_t + \beta_{\text{opt}} F_t$$

Initialization at t = 0:

 $X_0 = F_0 = \text{mean of first } n/3 \text{ actual sales (rounded up to integer) periods.}$ 

- (B) Linear trend
- (1) Linear time series regression:

$$F_t = a + b_t$$

where a and b are parameters estimated with OLSQ.

(2) Double exponential smoothing:

$$F_{t+p} = a_t + b_t p$$

$$Y'_t = \alpha_{\text{opt}} X_t + \beta_{\text{opt}} Y'_{t-1}$$

$$Y''_t = \alpha_{\text{opt}} Y'_t + \beta_{\text{opt}} Y''_{t-1}$$

$$a_t = 2Y'_t - Y''_t$$

$$b_t = (\alpha_{\text{opt}} | \beta_{\text{opt}}) (Y'_t - Y''_t)$$

where  $F_{t+p}$  = sales forecast p periods ahead made at time t.

Initialization at t = 0:

 $a_0$  and  $b_0$  parameter estimates obtained with OLSQ over the first n/3 (rounded up to integer) periods of sales. Then,

$$Y_0' = a_0 - (\beta_{\text{opt}}/\alpha_{\text{opt}})b_0$$
  
$$Y_0'' = a_0 - 2(\beta_{\text{opt}}/\alpha_{\text{opt}})b_0$$

- (3) Holt's two-parameter exponential smoothing. Same as Winters' multiplicative exponential smoothing (below), except that the terms for the seasonal factors were deleted.
- (C) Linear trend with seasonal component
- (1) Winters' multiplicative exponential smoothing:

$$F_t = (a + bt)s_t$$

where  $\alpha$ ,  $\beta$ ,  $\gamma$  are separately defined weighting constants, with each constrained to fall between 0 and 1.0,

$$a_{t} = \alpha_{\text{opt}}(X_{t}/s_{t-L}) + (1 - \alpha_{\text{opt}})(a_{t-1} + b_{t-1})$$

$$b_{t} = \beta_{\text{opt}}(a_{t} - a_{t-1}) + (1 - \beta_{\text{opt}})b_{t-1}$$

$$s_{t} = \gamma_{\text{opt}}(X_{t}/a_{t}) + (1 - \gamma_{\text{opt}})s_{t-L}$$

and all  $s_l$  adjusted such that  $\sum s_l = L$  for l = 1 to L, at each and every iteration. The forecast, made at time t, for any future period  $t + \tau$ , is:

$$F_{t+\tau} = (a + \tau b_t) s_{t+\tau-L}$$

Initialization at t = 0:

$$b_0 = \left(\frac{\sum_{i=L+1}^{2L} X_i}{L} - \frac{\sum_{i=1}^{L} X_i}{L}\right) / L$$

$$a_0 = \frac{\sum_{i=L+1}^{2L} X_i}{2L} - b_0 \frac{2L+1}{2}$$

$$s(i)_{j} = \left(\frac{X_{j}}{a_{0} + b_{0}t_{j}} + \frac{X_{j+L}}{a_{0} + b_{0}t_{j+L}}\right) / 2$$

where

j =the jth index,  $\sum j = L$ , and i =initial estimate.

- (D) Additive trend
- (1) Winters' additive exponential smoothing. Same as Winters' multiplicative exponential smoothing, except that addition and subtraction were substituted for multiplication and division, respectively.
- (E) Linear trend with seasonal component and cycle component
- (1) Decomposition—Method 1. An iterative model which uses one of the two deseasonalization schemes presented below, linear time series for assessing trend and the Winters' multiplication technique for assessing cycle.
- (2) Decomposition—Method 2. An iterative model which uses one of the two deseasonalization schemes, the linear time series model for assessing trend and any combination of procedures otherwise listed to assess periodic cycle.

- (F) Higher level trend
- (1) Quadratic time series regression:

$$F_{t} = a + bt + ct^{2}$$

$$an + b \sum t_{i} + c \sum t_{i}^{2} = \sum X_{i}$$

$$a \sum t_{i} + b \sum t_{i}^{2} + c \sum t_{i}^{3} = \sum t_{i}X_{i}$$

$$a \sum t_{i}^{2} + c \sum t_{i}^{3} + c \sum t_{i}^{4} = \sum t_{i}^{2}X_{i}$$
for  $i = 1$  to  $n$ 

Then, solve the last three above equations simultaneously for a, b and c.

(2) Quadratic exponential smoothing:

$$F_{t+p} = a_t + b_t p + c_t p$$

$$Y'_t = \alpha_{\text{opt}} X_t + \beta_{\text{opt}} Y'_{t-1}$$

$$Y''_t = \alpha_{\text{opt}} Y'_t + \beta_{\text{opt}} Y''_{t-1}$$

$$Y'''_t = \alpha_{\text{opt}} Y''_t + \beta_{\text{opt}} Y''_{t-1}$$

$$a_t = 3Y'_t - 3Y''_t + Y'''_t$$

$$b_t = (\alpha/2\beta^2) [(6 - 5\alpha_{\text{opt}}) Y'_t - 2(5 - 4\alpha_{\text{opt}}) Y''_t + (4 - 3\alpha_{\text{opt}}) Y''_t$$

$$c_t = (\alpha_{\text{opt}} |\beta_{\text{opt}})^2 (Y'_t - 2Y''_t + Y'''_t)$$

where

 $F_{t+p}$  = sales forecast p periods ahead made at time t.

Initialization at t = 0:

Use quadratic regression on first third of data to determine  $a_0$ ,  $b_0$  and  $c_0$ . Then, use the following to solve for  $Y'_0$ ,  $Y''_0$  and  $Y'''_0$ :

$$y_{t} = \begin{bmatrix} y'_{t} \\ y''_{t} \\ y'''_{t} \end{bmatrix} d = \begin{bmatrix} a_{t} \\ b_{t} \\ c_{t} \end{bmatrix} \quad \text{and } M = \begin{bmatrix} 1 & -\frac{\beta}{\alpha} & \frac{\beta(2-\alpha)}{2\alpha^{2}} \\ 1 & -\frac{2\beta}{\alpha} & \frac{2\beta(3-2\alpha)}{2\alpha^{2}} \\ 1 & -\frac{3\beta}{\alpha} & \frac{3\beta(4-3\alpha)}{2\alpha^{2}} \end{bmatrix}$$

Then,  $Y_0 = Md$ .

- (3) Logarithmic time series regression. Same as linear time series regression, except that the natural logarithm of all data were used as inputs, then antilogs were used to convert forecasts to original units.
- (G) General deseasonalization schemes for models
- (1) Classical deseasonalization:

$$S_{l} = \frac{\sum_{k=1}^{\left[(n-L)/L\right]^{*}} \left[ X_{lk} \div \binom{l+(L/2)-1}{X_{j}} + \frac{l+(L/2)}{X_{j}} \right] / 2L}{\left[(n-L)/L\right]^{*}}$$

\*rounded up to integer

l=1,2,...,L, and all  $s_l$  adjusted such that  $\sum s_l=L$ , for all l.

(2) Modified Census II deseasonalization. Corrects for trend bias in seasonal calculations and eliminates highest and lowest ratios as outliers for each seasonal calculation. Let:

I = n/L, and integer; IN = (I)(L); B = n - IN; j = I - 1. Then, slope:

$$b_1 = \left[ \left( \sum_{i=L+B+1}^{2L+B} X_i \atop L+B+1 \right) - \left( \sum_{i=B+1}^{L+B} X_i \middle| L \right) \right] \middle| L$$

$$b_{2} = \left[ \left( \sum_{i=2L+B+1}^{3L+B} X_{i} \atop X_{i} \atop L \right) - \left( \sum_{i=L+B+1}^{2L+B} X_{i} \atop L \right) \right] / L$$

$$b_{j} = \left[ \left( \sum_{i=IN-L+B+1}^{IN+B} X_{i} \middle| L \right) - \left( \sum_{i=(I-2)L+B+1}^{(I-1)L+B} X_{i} \middle| L \right) \right] \middle| L$$

Overall slope:

$$b = \frac{(b_1 + b_2 + \dots + b_j)}{(I-1)}$$

Intercept:

$$a = \left(\sum_{j=B+1}^{n} X - \sum_{j=B+1}^{n} X\right) / IN$$

For trend line (tr):

(a) For an even number of observations:

at time 
$$t = 1$$
,  $tr_1 = a + 1/2b$ ; for remaining  $t$ ,  $tr_t = tr_{t-1} + b$ 

(b) For an odd number of observations:

at time 
$$t = 1$$
,  $tr_1 = a + b$ ; for remaining  $t$ ,  $tr_t = tr_{t-1} + b$ 

Raw seasonal ratio:

$$(sr) = a_t/tr_t$$

Seasonal indices:

average of  $sr_l = a_l/tr_l$  for each l of L, with the min and max ratio excluded, then all seasonal indices  $(s_l)$  adjusted such that  $\sum s_l = L$ , for l = 1 to L.

#### APPENDIX 2: DISAGGREGATION METHODS

#### General notation

For a given product line:

 $P_{ii}$  = the proportion used to allocate product i's share of the total forecast at time t = 1, 2, ..., N

N = total number of products within the product line

$$t = 1, 2, ..., n$$

n = total number of time periods

 $X_{it}$  = actual sales for product i in period t

 $TO_t$  = total sales of all products within the product line in period t

$$= \sum_{i=1}^{N} X_{it}$$
 For  $t = 1, 2, ..., n$ 

$$PR_{it} = \frac{X_{it}}{TO_t}$$

# Disaggregation methods

Method A:

$$P_{it} = \sum_{t=1}^{n} \frac{X_{it}}{TO_t} / n$$

Method B1:

$$P_{it} = \frac{X_{i,t-1}}{TO_{t-1}} = PR_{i,t-1}$$

Method B2:

$$P_{it} = PR_{i,t-2}$$

Method B3:

$$P_{it} = PR_{i,t-3}$$

Method B4:

$$P_{it} = PR_{i,t-4}$$

Method C2:

$$P_{it} = \left\{ \frac{X_{i,t-1}}{TO_{t-1}} + \frac{X_{i,t-2}}{TO_{t-2}} \right\} \left| 2 = \left\{ \frac{PR_{i,t-1} + PR_{i,t-2}}{2} \right\} \right|$$

Method C3:

$$P_{it} = \left\{ \frac{PR_{i,t-1} + PR_{i,t-2} + PR_{i,t-3}}{3} \right\}$$

Method C4:

$$P_{it} = \left\{ \frac{PR_{i,t-1} + PR_{i,t-2} + PR_{i,t-3} + PR_{i,t-4}}{4} \right\}$$

Method D2:

$$P_{it} = \sum_{k=1}^{2} w_k P R_{i,t-k}$$

$$w_k = \frac{\operatorname{corr}(PR_{it}, PR_{i,t-k})}{\sum_{j=1}^{2} \operatorname{corr}(PR_{it}, PR_{i,t-j})}$$

Method D3:

$$P_{it} = \sum_{k=1}^{3} w_k PR_{i,t-k}$$

$$w_k = \frac{\operatorname{corr}(PR_{it}, PR_{i,t-k})}{\sum_{i=1}^{3} \operatorname{corr}(PR_{it}, PR_{i,t-j})}$$

Method D4:

$$P_{it} = \sum_{k=1}^{4} w_k PR_{i,t-k}$$

$$w_k = \frac{\text{corr}(PR_{it}, PR_{i,t-k})}{\sum_{i=1}^{4} \text{corr}(PR_{it}, PR_{i,t-j})}$$

Method E:

$$P_{it} = \sum_{k=1}^{4} B_k P R_{i,t-k}$$

 $B_k = OLSQ$  parameter estimates, subject to:

$$\sum_{k=1}^4 B_k = 1$$

Method F:

$$P_{it} = \frac{\sum_{t=1}^{n} X_{it}}{n} / \frac{\sum_{t=1}^{n} TO_{t}}{n}$$

Method G2:

$$P_{it} = \sum_{k=1}^{2} W_k P R_{i,t-k}$$

$$e_l = P R_{it} - P R_{i,t-l} \qquad l = 1, 2$$

$$W_1 = \frac{\text{var}(e_2) - \text{cov}(e_1, e_2)}{\text{var}(e_1) + \text{var}(e_2) - 2 \text{cov}(e_1, e_2)}$$

$$W_2 = \frac{\text{var}(e_1) - \text{cov}(e_1, e_2)}{\text{var}(e_1) + \text{var}(e_2) - 2\text{cov}(e_1, e_2)}$$

Method G3:

$$P_{it} = \sum_{k=1}^{3} W_k P R_{i,t-k}$$

$$e_l = P R_{it} - P R_{i,t-l} \qquad l = 1, 2, 3$$

$$W = (\hat{\Sigma}^{-1}1)/(1'\hat{\Sigma}^{-1}1)$$

$$W = \text{vector of weights}$$

$$\hat{\Sigma} = \text{variance-covariance structure of the errors, } e_l$$

$$1 = \text{column vector of unity}$$

Method H2:

$$P_{it} = \sum_{k=1}^{2} W_k P R_{i,t-k}$$

$$e_l = P R_{it} - P R_{i,t-l} \qquad l = 1, 2$$

$$W_1 = \text{var}(e_2) / \{ \text{var}(e_1) + \text{var}(e_2) \}$$

$$W_2 = \text{var}(e_1) / \{ \text{var}(e_1) + \text{var}(e_2) \}$$

Method H3:

$$P_{it} = \sum_{k=1}^{3} W_k PR_{i,t-k}$$

$$e_l = PR_{it} - PR_{i,t-l} \qquad l = 1, 2, 3$$

$$W_k = \{ var(e_k) \}^{-1} / \sum_{i=1}^{3} \{ var(e_i) \}^{-1}$$

Method I1:

$$P_{it} = PR_{i,t-a}$$

where

$$\max_{r=1 \text{ to } n} \left\{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \right\} = \operatorname{corr}(PR_{i,t-q})$$

Method I2:

$$P_{it} = \sum_{\substack{k=1\\l=q,s}}^{2} W_k P R_{i,t-l}$$

$$W_1 = \text{corr}(P R_{it}, P R_{i,t-q}) / \sum_{j=q,s} \text{corr}(P R_{it}, P R_{i,t-j})$$

$$W_2 = \text{corr}(P R_{it}, P R_{i,t-s}) / \sum_{j=q,s} \text{corr}(P R_{it}, P R_{j,t-j})$$

where:

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-q})$$

$$\max_{\substack{r=1 \text{ to } n \\ r \neq q}} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-s})$$

Method 13:

$$P_{it} = \sum_{\substack{k=1\\l=q,s,u}}^{3} W_k P R_{i,t-l}$$

$$W_1 = \text{corr}(P R_{it}, P R_{i,t-q}) / \sum_{\substack{j=q,s,u}} \text{corr}(P R_{it}, P R_{i,t-j})$$

$$W_2 = \text{corr}(P R_{it}, P R_{i,t-s}) / \sum_{\substack{j=q,s,u}} \text{corr}(P R_{it}, P R_{i,t-j})$$

$$W_3 = \text{corr}(P R_{it}, P R_{i,t-u}) / \sum_{\substack{j=q,s,u}} \text{corr}(P R_{it}, P R_{i,t-j})$$

where:

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-q})$$

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-s})$$

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-u})$$

#### Method I4:

$$P_{it} = \sum_{\substack{k=1\\l=q,s,u,v}}^{4} W_k P R_{i,t-l}$$

$$W_1 = \text{corr}(P R_{it}, P R_{i,t-q}) \Big| \sum_{\substack{j=q,s,u,v}} \text{corr}(P R_{it}, P R_{i,t-j})$$

$$W_2 = \text{corr}(P R_{it}, P R_{i,t-s}) \Big| \sum_{\substack{j=q,s,u,v}} \text{corr}(P R_{it}, P R_{i,t-j})$$

$$W_3 = \text{corr}(P R_{it}, P R_{i,t-u}) \Big| \sum_{\substack{j=q,s,u,v}} \text{corr}(P R_{it}, P R_{i,t-j})$$

$$W_4 = \text{corr}(P R_{it}, P R_{i,t-v}) \Big| \sum_{\substack{j=q,s,u,v}} \text{corr}(P R_{it}, P R_{i,t-j})$$

where:

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-q})$$

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-s})$$

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-u})$$

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-u})$$

$$\max_{r=1 \text{ to } n} \{ \operatorname{corr}(PR_{it}, PR_{i,t-r}) \} = \operatorname{corr}(PR_{i,t}, PR_{i,t-v})$$

#### ACKNOWLEDGEMENTS

Helpful criticism from two referees and the departmental editors (Johannes Ledolter and Robert Shumway) led to what we sincerely believe to be substantial improvements of an earlier version of this paper.

#### Authors' biographies

Charles W. Gross is Professor of Marketing at the Whittemore School of Business and Economics of the University of New Hampshire. He has published numerous articles, papers and books on sales forecasting and has extensive consulting experience in the field within a wide array of settings and organizations.

Jeffrey E. Sohl is Associate Professor of Management Science at the Whittemore School of Business and Economics of the University of New Hampshire. His primary research interest is in forecasting within the business environment and the public policy areas and has published several articles in these fields.
